(54) Title: **MONITORING QUALITY OF SERVICE IN PACKET-BASED COMMUNICATIONS**

(57) Abstract: A method of monitoring quality of service in communications over a packet-based network, involves transmitting test packets across the network and monitoring transmission characteristics such as packet loss and transmission delay for the test packets. A measure of network performance is then dynamically calculated from the transmission characteristics, and is displayed at the endpoint as a dynamic-indication of the network performance.

## **Monitoring Quality of Service in Packet-Based Communications**

### **Field of the invention**

5 The present invention relates to the monitoring of quality of service information in packet-based communications. The invention has particular application in packet-based telephony.

### **10 Background Of The Invention**

Many parameters such as network and codec delay, packet loss, codec performance affect the user's perception of the quality of service (QoS) of a packet-based telephony call, as compared to an end-to end TDM  
15 telephone call.

The Nortel Networks "Meridian" Internet Telephony Gateway Trunk ("Meridian" is a Trade Mark) can measure the latency and packet loss during a telephone call  
20 using the Internet Protocol. These factors directly affect the perceived QoS and can be used to generate a measurement of network performance during a call. If the measurement of network performance drops below a predetermined value, the system can be programmed to  
25 switch the call from the switched packet network to a conventional analog network, thereby ensuring that the user has an acceptable level of call quality at all times.

30 However, users do not themselves currently have any way of monitoring the QoS in an objective way. Users can only give subjective reactions that the QoS has improved or declined during a call.

This contrasts to GSM or other mobile communications, in which a single parameter, i.e. the strength of signal from the local base station, provides an accurate guide to the quality of the call, or in the case of two users each on mobile handsets, the quality at each end. Thus, many handsets have a signal strength indicator which allows a user to monitor the signal strength during a call. A method of monitoring QoS for a packet-based telephony call would be attractive to users and would add value to the network or equipment provider who is supplying the QoS information.

It is therefore an object of this invention to provide a method of monitoring quality of service in communications over a packet-based network.

#### **Summary of the Invention**

The invention provides a method of monitoring quality of service in communications over a packet-based network between two points, at least one of which is an endpoint, comprising the steps of:

- transmitting test packets across the network and
- monitoring transmission characteristics of said test packets;
- dynamically calculating from said transmission characteristics a measure of network performance; and
- providing at said endpoint a dynamic indication of the network performance based on said calculation.

It has been found that by measuring a few simple transmission characteristics such as packet loss and

transmission delay between endpoints, a useful measure of quality of service can be calculated and subsequently presented to a user at an endpoint, allowing the user to monitor the QoS as it varies in  
5 real time during the call. This gives the user added value for call set-up, as the QoS provided by different service providers can be compared. Alternatively, users might obtain rebates for call charges in respect of calls where the QoS was below a predefined level.  
10 It also benefits the suppliers of endpoint equipment, since a dynamic QoS monitoring feature will be attractive to customers of the equipment.

The presentation of this information can be by any useful means, such as: a green LED to indicate  
15 acceptable QoS and a red LED to indicate unacceptable QoS; a QoS indication bar on a handset or terminal display which varies in length as the QoS varies; an aural tone audible to the user when the QoS drops below a predetermined level; or a numerical display providing  
20 a numerical indication of QoS on a scale of e.g. 1-5, to give but a few examples.

An important application of the invention is in voice telephony calls made over an IP (Internet Protocol) based network such as the Internet, or over a local  
25 area network which operates in much the same way as the Internet (e.g. a local area network or LAN). This type of telephony is referred to as Voice over Internet Protocol or VoIP telephony.

30 In VoIP calls, the voice signals are converted into a series of discrete packets of data. The packets which

include addressing information, are sent independently of one another over the network, passing through a series of nodes from source to destination. Two consecutive packets might follow entirely different routes to the destination, and if it happened that one route was more congested than the other, packets on the congested route could be delayed or lost. Accordingly each packet of data includes not only the voice signal data and the addressing information, but also sequencing information to enable the computer which receives the individual data packets to piece them back together in the correct order and recreate the original voice signal.

As packets can be lost when travelling the network or as they can be delayed (depending on the route travelled, which is not a fixed route), the percentage packet loss and the delay time of packets travelling from source to destination are the two transmission characteristics most likely to vary in real time and have a noticeable effect on the QoS.

Accordingly, in addition to the voice signal packets, the invention involves also sending a series of test packets. In one embodiment, the test packets are sent from source to destination and then returned. By measuring how many packets are not returned, a measure of percentage packet loss for these test packets can be calculated. In statistical terms this percentage packet loss will apply equally to the voice signal packets which were sent during the same time period, and thus the percentage figure for the test packets

provides a measure of how many voice signal packets have been lost.

Preferably, therefore, the test packets include a first series of test packets which issue from a source location to a destination location and a second series of test packets which issue from the destination location to the source location in response to the first series of test packets, whereby the network characteristics may be monitored by comparing the first and second series of test packets.

One can regard the second series of test packets as being the first series "bounced back" from the destination, or as being new packets generated by the destination location; the difference is not material to the invention.

A measure of packet loss is obtained by comparing the packets issued from the source location and the packets received back at the source location.

The first series of test packets will preferably include local source timestamp information and the second series of test packets will preferably include local destination timestamp information, the difference between the source and destination timestamp information being used to calculate a delay characteristic of the network.

This delay characteristic is preferably the absolute delay in echo-free connections ( $T_a$ ) between the source and destination locations over the network.

Technology is currently in place to generate synchronised timestamps on individual data packets at different locations within the network. The Internet Engineering Task Force (IETF) has an approved method of  
5 gaining accurate time stamp information from a centralised time server on a network (IETF Network Time Protocol - RFC 1305). Data packets can be issued from a source location with local source timestamp information, and sent between nodes on the network at  
10 regular intervals. On receipt by a node they are immediately bounced back to the originator with local timestamp information added. This allows the value of  $T_a$  to be calculated.

Voice quality on a packet network is dependent on a  
15 large number of factors, a list of which is given in ITU-T Recommendation G.107 version 05/00 (issued by the Telecommunication Standardization Sector of the International Telecommunication Union). No one factor exclusively determines voice quality - it is the  
20 combined effect of these factors that determines the overall voice quality.

The invention takes advantage of the fact that those factors which vary in a real-time way are largely  
25 dependent on a few simple transmission characteristics of packets travelling between the two parties.

ITU-T Recommendation G.107 provides a computational model, the E-Model, to determine the combined effect of  
30 various parameters on voice quality. The model evaluates the end-to-end network transmission performance and outputs a scalar rating "R" for the

network transmission quality. The model further correlates the network objective measure, "R", with the subjective QoS metric for voice quality, MOS. The MOS or Mean Opinion Score is a subjective measurement of voice quality, and ranges from 1 to 5, where 1 is bad voice quality and 5 is excellent.

The value of R depends on a wide range of factors: Sending Loudness Rating; Receiving Loudness Rating; 10 Sidetone Masking Rating; Listener Sidetone Rating; D-Value of Telephone, Send Side; D-Value of Telephone Receive Side; Talker Echo Loudness Rating; Weighted Echo Path Loss; Mean one-way Delay of the Echo Path; Round Trip Delay in a 4-wire Loop; Absolute Delay in 15 echo-free Connections; Number of Quantization Distortion Units; Equipment Impairment Factor; Circuit Noise referred to 0 dBr-point; Noise Floor at the Receive Side; Room Noise at the Send Side; Room Noise at the Receive Side; and Advantage Factor. . All of 20 these factors are detailed more clearly in the ITU-T Recommendation G.107, and are used to calculate R.

Recommendation G.107 provides the following general formula for R:

$$R = R_o - I_s - I_d - I_e + A$$

$R_o$  is the basic signal-to-noise ratio, including noise sources such as circuit noise and room noise.  $I_s$  is a combination of all impairments which occur more or less 30 simultaneously with the voice signal.  $I_d$  represents the impairments caused by delay. The term  $R_o$  and the  $I_s$  and  $I_d$  values are subdivided into further specific impairment values. The Recommendation give the formulae

used in the E-model to generate  $R_o$ ,  $I_s$ ,  $I_d$ , based on the wide range of factors listed above.

5 The equipment impairment factor  $I_e$  represents impairments caused by low bit rate codecs and packet losses over the network, and is discussed below.

10 The advantage factor  $A$  allows for compensation of impairment factors when there are other advantages of access to the user. A user on a conventional wirebound call can expect higher clarity of signal than a user on a satellite call in a remote uninhabited location, for example. This means that the satellite user is prepared to put up with a lower QoS than the wirebound  
15 user. Because the E model is intended to be used to correlate the network objective measure,  $R$ , with a subjective MOS score,  $R$  is weighted by the advantage factor to take into account this psychological expectation factor or advantage factor  $A$ .

20 Examples given for maximum values of  $A$  are: Conventional (wirebound) telephony,  $A=0$ ; the advantage of mobility by cellular networks in a building gives  $A=5$ ; the advantage of mobility in a geographical area or moving in a vehicle gives  $A=10$ ; the advantage of  
25 access to hard-to-reach locations, e.g. via multi-hop satellite connections gives  $A=20$ . These values are provisional only.

30 Deriving  $I_e$  in real-time from packet loss and the codec type:

In a packet based network, such as an IP Network, the equipment impairment factor ( $I_e$ ) is specifically

related to the communications codec type chosen for the call and the packet loss incurred across the network. Packet loss can be incurred due to network congestion or equipment out of service and subsequent failover. By  
5 empirical measurement of MOS scores (i.e. the users' perception of quality of service for different percentage packet loss values, all other factors being equal) under test conditions for specific test induced packet loss or otherwise it is possible to tabulate the  
10 Ie for percentage packet loss criteria for the codec types used by the equipment. These tables may then be used in real-time to derive a value for Ie based on the real-time measurement of packet loss in the network and for the codec type in use at that time.

15

The factor Id was mentioned above as representing the impairments caused by delay. It is composed of impairments due to Talker Echo (Idte), impairments due to Listener Echo (Idle), and impairments caused by too-  
20 long absolute delay Ta, which occur even with perfect echo cancelling (Idd). Idd is the factor which is most important in terms of variations during a call which have a significant effect on QoS.

25 Deriving Idd in real-time:

For packet based networks, such as an IP network, the Absolute Delay in echo-free Connections (Ta) is specifically related to the impairments represented by the factor Idd. Ta can vary in real-time due to the  
30 dynamic nature of packet based networks, which allow multiple routes between destinations and each packet may be routed via different physically equipment

depending on various network factors such as instantaneous load or equipment out of service.

To measure  $I_{dd}$ , bursts of packets containing timestamp information gained from a centralised time server, using protocols such as the IETF Network Time Protocol - RFC 1305, are exchanged between nodes on the network at regular intervals. On receipt by a node they are immediately bounced back to the originator with local timestamp information added, and from the two timestamps, the absolute delay in echo-free connections ( $T_a$ ) is calculated. These same packets are also used to detect lost packets as described above.

The delay impairment factor ( $I_{dd}$ ) is given by the formulae:

(i) for  $T_a < 100\text{ms}$ ,  
 $I_{dd} = 0$ ; and

(ii) for  $T_a \Rightarrow 100 \text{ ms}$ ,  
 $I_{dd} = 25 * ((1+X)^{1/6} - 3 * (1+(X/3)^6)^{1/6} + 2)$

Where  $X = (\log(T_a/100)) / \log(2)$

## 25 Derivation of R from $I_e$ and $I_{dd}$

From the formula given above for R:

$$R = R_o - I_s - I_d - I_e + A$$

30 a real-time value for R can be derived if assumptions are made that  $R_o$ ,  $I_s$  and A have fixed values, and that

the components Idte and Idle are also fixed for the duration of a call.

Recommendation G.107 gives default values for all of  
5 the factors mentioned in the Recommendation, but these defaults can be varied to take account of equipment-specific, network-specific, or environment-specific parameters. Using the default values given, one arrives at a figure of  $R=93.2$ , indicating very high  
10 voice quality.

We have found that for a VoIP implementation over a Wide Area Network (WAN) using the Nortel Networks Meridian Integrated IP Telephony Gateway product  
15 family, the generalised formula for  $R$  can be replaced by:

$$R = Y - (Ie + Idd)$$

with a value of  $Y = 94.5$  which is the laboratory  
20 measured figure for all the non-realtime varying parameters.

The constant  $Y$  is higher than the default of  $R = 93.2$ , but is adjusted downwards by the combined effects of  
25 packet loss and absolute delay. Different equipment may result in a different value being chosen for the constant other than 94.5.

The value of  $Y$  is preferably from about 92 to about 98, more preferably from about 93 to about 96.

Calculation of MOS score from R

Since R is an objective rather than a subjective measure of QoS, the calculated value of R is preferably correlated to a subjective metric for the quality of service, and an indication of this subjective value is provided to the user. Recommendation G.107 provides a formula for deriving the subjective Mean Opinion Score (MOS) from the R value:

$$\text{MOS} = 1 + 0.035R + R(R-60)(100-R)(7 \times 10^{-6})$$

The value of R should first be checked to ensure it is in the range 1 to 100. If R is less than zero, MOS is set at 1 and if R is greater than 100, MOS is set at 4.5.

The MOS scale lies from 1 to 5, but scores below 2 or 3 may effectively indicate QoS so low as to be unacceptable. Accordingly, MOS scores in the range e.g. 2.5 to 5 can be normalised in the method of the invention to a more useful indication. An example might be to emit a warning tone or illuminate a warning LED on the handset if the MOS drops below 3, for example. Alternatively, the calculated MOS scores can be normalised so that values indicating acceptable call quality (e.g. from 2.5 or 3 to 4.5 or 5) are expanded out to a five or ten point scale.

The method of the invention may also include the step of providing, at the request of a user, an indication of one or more of said transmission characteristics.

This user request may be made by means of an input device associated with the endpoint and the indication may be provided by means of a display device associated with the endpoint.

- 5 For example, the endpoint may be a computer terminal having a microphone and speaker associated with it, which acts as a telephone when the required software is running on the computer. In such cases, a menu could be provided for the user to call up individual  
10 transmission characteristics such as percentage packet loss (current or historical) and absolute one-way delay times from endpoint to endpoint (or if the other endpoint is connected to the packet-based network by means of a conventional PSTN and a gateway, the delay  
15 point time from the user's endpoint to the gateway at the other end of the call).

Other parameters available to the endpoint could also be called up by the menu, such as the codec being used. The output device could be the computer VDU.

- 20 Alternatively, the endpoint might be an ethernet telephony set which connects directly to the network, in which case, the input device could be the telephony set keypad, and the display device an LCD display on the handset.

- 25 The method may also include the step of logging the network transmission characteristics, or of logging the results of the calculations of network performance.

Optionally, the logging might occur only when the results are within a predetermined range. An example might be a system which monitors the network performance, displays a red light or emits a warning  
5 beep when the QoS drops below an acceptable level, and records this event in a log. The user might then be able to obtain a rebate for the call, or for part of the call charge.

The logging could also include logging an occurrence of  
10 a communications connection over the network being lost, i.e. if a call has been dropped as a result of a deterioration in network performance.

The method of the invention can also include adjusting a billing record for the user in dependence on the  
15 results of said calculation. Thus, the service provider might automatically adjust charges for the user based on a below-acceptable level of QoS.

In a further aspect the invention provides a computer program which when executed causes a computer  
20 associated with the endpoint to:

monitor transmission characteristics of test packets transmitted across the network;

dynamically calculate from the transmission characteristics a measure of network performance; and

25 provide the user with a dynamic indication of the network performance based on the calculation.

The computer program can operate the method of the invention as detailed above, and can also be  
30 responsible for aspects of billing and logging.

The invention further provides a telephone handset for connection to a packet-based network, having a display device for displaying a dynamic indication of network performance based on the transmission characteristics of test packets transmitted across a network to which the handset is attached.

The handset will preferably further include a processor for calculating a measure of network performance based on the transmission characteristics of test packets transmitted by the handset across the network.

In a further aspect the invention provides a system for monitoring quality of service in communications over a packet-based network, comprising:

a source endpoint connected to the network via which a user may transmit communication signals over the network;

a test packet generator for transmitting test packets across the network

a test packet receiver for receiving test packets from the network;

a processor for measuring transmission characteristics of the test packets and for calculating from said transmission characteristics a measure of network performance; and

an output device associated with the endpoint for providing a dynamic indication of the network performance based on said calculation.

Preferably, the test packet generator includes a timestamp generator for adding a local source timestamp to the test packets.

Further, preferably, the system includes a destination  
5 endpoint with which the source endpoint is in communication over the network, the destination endpoint having associated therewith: a test packet receiver for receiving test packets from the network; a timestamp generator for adding a local destination  
10 timestamp to the received test packets; and a test packet re-transmitter for re-transmitting the received test packets with the local destination timestamp back to their source.

The system may also include a centralised time server  
15 in communication with the network for generating a standardised time and providing this to the source and destination endpoints.

#### **Brief Description of Drawings**

20 The invention will now be illustrated by the following descriptions of embodiments thereof given by way of example only with reference to the accompanying drawings, in which:

25 Fig. 1 is an architecture of a system according to the invention;

Fig. 2 is a flowchart illustrating the steps carried out in a preferred embodiment of the method of the  
30 invention; and

Fig. 3 is a schematic view of a handset according to the invention.

#### **Detailed Description of Preferred Embodiments**

5 Fig. 1 shows a packet-based network 10, comprising a number of inter-connected nodes 12. The network may be the Internet, or it may be any other packet-based network. A pair of call servers 14, 16 are connected to nodes 12 of the network. Each call server has a  
10 number of terminals or handsets 18 associated with it, from which users may make telephone calls over the network. The handsets 18 are connected directly to nodes 12 of the network and are logically connected to the respective call servers 14,16. In Fig. 1 only a  
15 single handset 18 is shown for each call server, and the logical connection is denoted by a dotted line. For convenience, server 14 is referred to as the source call server, and server 16 as the destination call server.

20

The servers and handsets may be replaced by computers connected to the network having associated ethernet handsets.

25 The computers could also be used for video-conferencing or other network-based communications, to which the invention would be equally applicable.

Also connected to the network 10 is a centralised time  
30 server 20, which enables both servers 14,16 to generate synchronised timestamps, in accordance with IETF Network Time Protocol RFC 1305.

Referring additionally to Fig. 2, when a VoIP call is made between the two handsets 18 (step 22), both handsets begin the transmission and receipt of signal packets, in the normal way, step 24. The source server 5 14 also begins transmission and receipt of test packets, step 26. The destination server could also begin its own transmission of test packets. (The test packets could instead be transmitted directly to or from the handsets, if the handsets are provided with 10 the necessary functionality to generate such test packets.)

The test packets include source and destination header information allowing them to be routed to the 15 destination server by the intervening nodes in the network, and returned back to the source. The test packets also contain timestamp information indicating the time of transmission from the source, as synchronised with time server 20. When the destination 20 server receives a test packet it timestamps it with the time of receipt at the destination server 16, and re-routes it with this additional information back to the source.

25 The source call server 14 monitors the percentage of packets returned in this way, and derives a percentage value for packets lost, step 28. Controlling software running on the server 14 then correlates this percentage with the codec being used for the call in a 30 correlation table (step 30) and reads from this table a value for the equipment impairment factor Ie. This table will be stored on the server, and the table will have been calibrated beforehand under test conditions

to provide the correct  $I_e$  value for all of the codecs used by the server in making calls.

The  $I_e$  value is then stored for later calculations,  
5 step 32.

When the test packets are received back with the destination time stamp information, step 26, the software on the server makes a parallel calculation of  
10 the average one-way total transmission delay ( $T_a$ ) for the packets received back during a short period of time, step 34.

The value of  $T_a$  is then examined to see if it is less  
15 than 100 ms, step 36. If so, then the variable  $I_{dd}$  is set at zero, step 38, to reflect the fact that the algorithm delay times of less than 100 ms as being acceptable for high-quality voice calls.

20 If  $T_a$  is equal to or greater than zero, then a value for  $I_{dd}$  is calculated according to the formulae:

$$I_{dd} = 25 * ((1 + X^6)^{1/6} - 3 * (1 + (X/3)^6)^{1/6} + 2)$$

25 Where  $X = (\log(T_a/100))/\log(2)$

These formulae are calculated in reverse order, naturally, with  $X$  being determined in step 40 and  $I_{dd}$  in step 42.

30 The stored values of  $I_e$  and  $I_{dd}$  are then used to calculate  $R$  (step 44) according to the formula:

$$R = Y - I_{dd} - I_e,$$

with Y set at a value of 94.5 (a value previously obtained during testing for a Nortel Networks Meridian  
5 IP Telephony Gateway conducting VoIP calls). Different equipment set-ups might use different values for Y.

The value thus derived for R is converted to more subjective MOS score (step 46) according to the  
10 formula:

$$MOS = 1 + 0.035R + R(R-60)(100-R)(7 \times 10^{-6})$$

(Optionally, in accordance with Recommendation G.107,  
15 the value of R can first be filtered to check if it is in the range 1 to 100. If R is less than zero, MOS is set at 1 and if R is greater than 100, MOS is set at 4.5. In practice, this step may be unnecessary, since the R values for any useful figures of packet loss and  
20 delay will always be in the range of zero to 100).

The MOS scale lies from 1 to 5, but scores below 2 or 3 may effectively indicate QoS so low as to be unacceptable. Accordingly, MOS scores in the range  
25 e.g. 2.5 to 5 can be normalised (step 48) to a zero to 5 point scale for display purposes. MOS scores of 2.5 or less are normalised to zero, and higher scores are converted according to the following table:

CALCULATED MOS SCORE	NORMALISED DISPLAY VALUE
2.5 - 3.0	1
3.0 - 3.5	2
3.5 - 4.0	3
4.0 - 4.5	4
4.5 - 5.0	5

The display values are then output to a display unit (step 50) on the handsets 18, an example of which is shown in Fig. 3. The handset includes a conventional keypad array 60 and a cradle 62 for a conventional handheld unit (not shown) incorporating earpiece and mouthpiece. The handset also includes a built-in loudspeaker 64 and a display unit 66.

10

Display unit 66 displays information relating to the call, such as internal line number and dialled number (or the number of the calling party, if the call was received rather than initiated from the handset shown). The display unit further shows a series of five indicator bars 68a-68e to indicate the QoS display value as calculated in the method of Fig. 2. This is shown as "QoS strength" which in fact is a measure of the system parameters as predetermined by the constant value of 94.5, and more particularly of the dynamic variations from the optimum QoS due to packet losses and transmission delays.

15  
20

In the handset shown in Fig. 3, indicator bars 68a-68c are darkened to indicate a display value of 3, corresponding to a MOS value of 3.5-4.0, which is a relatively high quality voice signal.

25

Returning to Fig. 2, the software enters a continuous loop by checking whether the call is still active (step 52), and if so, returning to steps 28 and 34 for further updating of the display value in the light of current delays and packet losses.

The invention is not limited to the embodiments described herein which may be varied without departing from the spirit of the invention.

What is claimed is:

1. A method of monitoring quality of service in communications over a packet-based network between two points, at least one of which is an endpoint, comprising the steps of:

transmitting test packets across the network and monitoring transmission characteristics of said test packets;

10 dynamically calculating from said transmission characteristics a measure of network performance; and

providing at said endpoint a dynamic indication of the network performance based on said calculation.

2. A method according to claim 1, wherein said transmission characteristics are selected from packet loss, transmission delay, and a combination thereof.

3. A method according to claim 2, wherein said transmission characteristics include both packet loss and transmission delay.

20 4. A method according to any preceding claim, wherein the indication of the network performance is provided by means of a visual display associated with the endpoint.

5. A method according to any of claims 1 to 3, wherein the indication of the network performance is provided by means of an aural signal provided to the endpoint.

6. A method according to claim 5, wherein the aural indication of the network performance is provided as a discrete signal emitted at the endpoint when the value of the metric passes a predetermined point.

5 7. A method according to any preceding claim, wherein said test packets include a first series of test packets which issue from a source location to a destination location and a second series of test  
10 said source location in response to said first series of test packets, whereby said network characteristics may be monitored by comparing the first and second series of test packets.

8. A method according to claim 7, wherein the first  
15 series of test packets include local source timestamp information and wherein the second series of test packets include local destination timestamp information, the difference between said local source timestamp information and local destination timestamp  
20 information being used to calculate a delay characteristic of the network.

9. A method according to claim 8, wherein the delay characteristic is the absolute delay in echo-free  
25 connections ( $T_a$ ) between the source and destination locations over the network.

10. A method according to any of claims 7 to 9, wherein a measure of packet loss is obtained by comparing the packets issued from the source location and the packets received back at the source location.

11. A method according to claim 9, wherein a measure of packet loss is obtained by comparing the packets issued from the source location and the packets received back at the source location.

5 12. A method according to claim 11, wherein the measure of packet loss and the identity of the communications codec being employed by the endpoint are used to calculate an equipment impairment factor (Ie).

10 13. A method according to claim 12, wherein the calculation of Ie is made by looking up the measured packet loss in a stored table which correlates values of Ie with packet loss values for the codec being used.

14. A method according to claim 11, wherein the calculated value of Ta is used to calculate a delay  
15 impairment factor.

15. A method according to claim 14, wherein the delay impairment factor (Idd) is given by the formulae:

(i) for  $T_a < 100\text{ms}$ ,  
20  $I_{dd} = 0$ ; and

(ii) for  $T_a \Rightarrow 100\text{ ms}$ ,  
$$I_{dd} = 25 * ((1 + X^6)^{1/6} - 3 * (1 + (X/3)^6)^{1/6} + 2)$$

25 Where  $X = (\log(T_a/100))/\log(2)$

16. A method according to claim 15, wherein a transmission rating factor R is calculated from the

formula  $R = Y - I_{dd} - I_e$ , where Y is a constant which has been predetermined for the network and the equipment being used on the network, and wherein  $I_e$  is an equipment impairment factor calculated from the measure of packet loss and the identity of the communications codec being employed by the endpoint.

17. A method according to claim 16, wherein the calculation of  $I_e$  is made by looking up the measured packet loss in a stored table which correlates values of  $I_e$  with packet loss values for the codec being used.

18. A method according to claim 17, wherein the value of Y is from about 92 to about 97.

19. A method according to claim 18, wherein the value of Y is from about 93 to about 95.

20. A method according to claim 19, wherein the value of Y is about 94.5.

21. A method according to claim 16, wherein the calculated value of R is correlated to a subjective metric for the quality of service, and wherein an indication of the value of said subjective metric is provided at the endpoint to a user.

22. A method according to claim 21, wherein said metric is a mean opinion score (MOS) and is calculated according to the formula:

$$\text{MOS} = 1 + 0.035R + R(R-60)(100-R)(7 \times 10^{-6})$$

23. A method according to claim 22, wherein said MOS is further adjusted before being provided as an

indication at the endpoint, by normalising acceptable values of MOS to a different scale.

24. A method according to claim 21, wherein the indication of the value of the subjective metric is provided by means of a visual display associated with the endpoint.

25. A method according to claim 21, wherein the indication of the value of the subjective metric is provided by means of an aural signal provided to the endpoint.

26. A method according to claim 25, wherein the aural indication is provided as a discrete signal emitted at the endpoint when the value of the metric passes a predetermined point.

27. A method according to any preceding claim, wherein the step of providing a dynamic indication of the network performance includes providing, at the request of a user, an indication of one or more of said transmission characteristics.

28. A method according to claim 27, wherein the request of the user is made by means of an input device associated with the endpoint and the indication is provided by means of a display device associated with the endpoint.

29. A method according to any preceding claim, further comprising the step of logging the network transmission characteristics.

30. A method according to any preceding claim, further comprising the step of logging the results of said calculation.

31. A method according to claim 30, wherein the step  
5 of logging the results of said calculation occurs only when said results are within a predetermined range.

32. A method according to claim 30, wherein the step  
of logging also includes logging the fact that a  
communications connection over the network has been  
10 lost.

33. A method according to any preceding claim, further comprising the step of adjusting a billing record for a user in dependence on the results of said calculation.

15 34. A computer program product in machine readable form containing instructions which when executed cause a computer associated with an endpoint connected to a packet-based network to:

monitor transmission characteristics of test  
20 packets transmitted across the network;

dynamically calculate from said transmission characteristics a measure of network performance; and

provide to said endpoint a dynamic indication of the network performance based on said calculation.

25 35. A computer program product according to claim 34, wherein said transmission characteristics are selected from packet loss, transmission delay, and a combination thereof.

36. A computer program product according to claim 35, wherein the transmission characteristics include the absolute delay in echo-free connections ( $T_a$ ) between source and destination locations over the network,  
5 obtained by comparing local timestamp information from source and destination locations on the network and a measure of packet loss obtained by comparing the packets issued from the source location and the packets received back at the source location.

10 37. A computer program product according to claim 36, wherein the measure of packet loss and the identity of the communications codec being employed by the endpoint are used to calculate an equipment impairment factor ( $I_e$ ).

15 38. A computer program product according to claim 37, wherein a delay impairment factor ( $I_{dd}$ ) is given by the formulae:

(i) for  $T_a < 100\text{ms}$ ,  
20  $I_{dd} = 0$ ; and

(ii) for  $T_a \geq 100 \text{ ms}$ ,  
$$I_{dd} = 25 * ((1 + X^6)^{1/6} - 3 * (1 + (X/3)^6)^{1/6} + 2)$$

25 Where  $X = (\log(T_a/100)) / \log(2)$

39. A computer program product according to claim 38, wherein a transmission rating factor  $R$  is calculated from the formula  $R = Y - I_{dd} - I_e$ , where  $Y$  is a constant which has been predetermined for the network  
30 and the equipment being used on the network, and

wherein  $I_e$  is an equipment impairment factor calculated from the measure of packet loss and the identity of the communications codec being employed by the endpoint.

40. A computer program product according to claim 39,  
5 wherein the value of Y is from about 92 to about 97.

41. A computer program product according to claim 40,  
wherein the value of Y is from about 93 to about 95.

42. A computer program product according to claim 41,  
wherein the value of Y is about 94.5.

10 43. A computer program product according to claim 39,  
wherein the calculated value of R is correlated to a  
subjective metric for the quality of service, and  
wherein an indication of the value of said subjective  
metric is provided at the endpoint to a user.

15 44. A computer program product according to any of  
claims 34 to 43, wherein provision of a dynamic  
indication of the network performance includes  
providing, at the request of a user, an indication of  
one or more of said transmission characteristics.

20 45. A computer program product according to any of  
claims 34 to 44, further comprising instructions which  
when executed cause a computer to log the network  
transmission characteristics.

46. A computer program product according to any of  
25 claims 34 to 45, further comprising instructions which  
when executed cause a computer to log the results of  
said calculation.

47. A computer program product according to any of claims 34 to 46, further comprising instructions which when executed cause a computer to adjust a billing record for the a in dependence on the results of said calculation.

48. A telephone handset for connection to a packet-based network, having a display device for displaying a dynamic indication of network performance based on the transmission characteristics of test packets transmitted across a network to which the handset is attached.

49. A telephone handset according to claim 48, further comprising a processor for calculating a measure of network performance based on the transmission characteristics of test packets transmitted by the handset across the network.

50. A system for monitoring quality of service in communications over a packet-based network, comprising:  
a source endpoint connected to the network via which a user may transmit communication signals over the network;

a test packet generator for transmitting test packets across the network

a test packet receiver for receiving test packets from the network;

a processor for measuring transmission characteristics of said test packets and for calculating from said transmission characteristics a measure of network performance; and

an output device associated with said endpoint

for providing a dynamic indication of the network performance based on said calculation.

51. A system according to claim 50, wherein said test packet generator includes a timestamp generator for  
5 adding a local source timestamp to said test packets.

52. A system according to claim 51, further comprising a destination endpoint with which said source endpoint is in communication over the network, said destination endpoint having associated therewith:  
10 a test packet receiver for receiving test packets from the network; a timestamp generator for adding a local destination timestamp to said received test packets; and a test packet re-transmitter for re-transmitting said received test packets with said local destination  
15 timestamp back to their source.

53. A system according to claim 52, further comprising a centralised time server in communication with the network for generating a standardised time and providing same to said source and destination  
20 endpoints.

54. A packet-based communications network comprising a system for monitoring quality of service as claimed in claim 50.

(54) Title: MONITORING QUALITY OF SERVICE IN PACKET-BASED COMMUNICATIONS

(57) Abstract: A method of monitoring quality of service in communications over a packet-based network, involves transmitting test packets across the network and monitoring transmission characteristics such as packet loss and transmission delay for the test packets. A measure of network performance is then dynamically calculated from the transmission characteristics, and is displayed at the endpoint as a dynamic indication of the network performance.
